Indoor Millimeter-Wave Systems: Design and Performance Evaluation

Jacek Kibilda, Allen B. MacKenzie, Mohammad J. Abdel-Rahman, Seong Ki Yoo, Lorenzo Galati Giordano, Simon L. Cotton, Nicola Marchetti, Walid Saad, William G. Scanlon, Adrian Garcia-Rodriguez, David López-Pérez, Holger Claussen, and Luiz A. DaSilva

Abstract

Indoor areas, such as offices or shopping malls, are a natural environment for initial millimeter-wave (mmWave) deployments. While we already have the technology that enables us to realize indoor mmWave deployments, there are many outstanding challenges associated with system-level design and planning for such. The objective of this manuscript is to bring together multiple strands of research to provide a comprehensive and integrated framework for the design and performance evaluation of indoor mmWave systems. The paper introduces the framework with a status update on mmWave technology, including ongoing 5th Generation wireless (5G) standardization efforts, and then moves on to experimentally-validated channel models that inform performance evaluation and deployment planning. Together these yield insights on indoor mmWave deployment strategies and system configurations, from feasible deployment densities to beam management strategies and necessary capacity extensions.

I. INTRODUCTION

Our motivation behind this manuscript is to present a comprehensive framework for performance evaluation and design practices dedicated to indoor mmWave networks. The framework integrates inputs from multiple areas of mmWave networking expertise, from standardization, to channel measurements and modelling, to system-level evaluations and deployment planning. Its major contribution is insights into indoor mmWave deployment planning strategies and system configurations that are grounded and informed by experimentally-validated channel models.

mmWaves are a natural choice for mobile indoor deployments due to much shorter link distances, weak penetration through walls, and large available bandwidths. In fact, the concept of using mmWaves to provision multi-Gbps speeds over indoor areas dates back to works published in the late 90's [1], [2]. A decade later came a suite of standards that offered the possibility of ad hoc networking, including ECMA-387 [3], IEEE 802.15.3c [4], and IEEE Wireless Gigabit 802.11ad/ay [5], [6]. But it is only recently that mmWave mobile broadband networking came into prominence with the arrival of 5G wireless [7], [8].

At the time of writing, the first set of 5G-New Radio (NR) specifications had already been defined as part of the 3rd Generation Partnership Project (3GPP) Release 15, functionally frozen in September 2018. Work on Release 16 is ongoing and is planned to be frozen in March 2020, with Release 17 to follow. The Frequency Range (FR) considered for deploying mmWave technology, as agreed in Release 15, is from 24.25 GHz to 52.6 GHz, also referred to as FR2¹. FR2 currently addresses three bands: 24.25–27.5 GHz (n257), 26.5–29.5 GHz (n258), 37–40 GHz (n260), all meant to support time division duplex (TDD) operation only. Usage of frequencies between 52.6 GHz and 71 GHz is currently under study in Release 17. In particular, the spectrum around 60 GHz presents an attractive use case, as it: a) does not require licenses, and b) is harmonised globally [9]. In this spectrum, the 3GPP is planning to deploy NR-based access technology – NR–Unlicensed (NR-U) – which will incorporate extensions necessary to work in unlicensed spectrum. NR-U will account for national restrictions of the 60 GHz band, which the 3GPP had already identified in Release 14 [10].

As part of its 5G activity, the 3GPP defined the enhanced Mobile Broadband (eMBB) Indoor Hotspot scenario as a natural case study for indoor mmWave mobile networks [11]. The key purpose of this scenario is to provision small-cell coverage of high data rates and capacity to

¹FR 1 addresses the spectrum between 410 MHz and 7.125 GHz.

Fig. 1. Status of the millimeter-wave spectrum for 5G-NR.

a user population within a confined area. Typical examples for this type of scenario include an open office, airport hall, or shopping mall with access points mounted either on the ceiling or walls at a small height above ground level. For such a setup, one would be interested in understanding the required density of access points, deployment locations, and effective network settings. Understanding these system design aspects requires adequate system-level evaluation that involves similarly adequate representation of the mmWave channel.

There are many ongoing measurement campaigns being conducted around the globe with the aim of characterizing and modeling the mmWave propagation channel, e.g., [12]–[16]. By their nature, all these measurements are context-specific (as any experimental work), and, depending on the modeling technique used, pertain to different types of system-level evaluations. For example, in an open office scenario, radio infrastructure is typically mounted to the ceiling or walls, illuminating the main area inside [17]. In such a setup, the main factor limiting signal propagation is shadowing by physical objects [18]. In particular, human bodies introduce extra attenuation, referred to as body blockage, which may vary with the orientation and position of the bodies with respect to both the device and the serving access point [19]. However, whether the communication link is blocked or not will also have a discernible effect on the fading characteristics of the associated wireless channel. Broadly speaking, blocked links often display a richer multipath structure, with weaker direct component and larger delay spread, than the unobstructed ones [14]. Moreover, it was found that within indoor locations, such as large offices and hallways, body-related blockage has a less pronounced effect on the received signal power, most likely due to the increased scattering in the environment [19]. The trick is to capture all of these propagation-related effects in a model that is both accurate and amenable to the analysis at system-level.

In what follows we describe our framework by first discussing our channel measurement campaign and a modelling approach that we subsequently integrate into both system-level

evaluations and deployment planning. Using this framework, we provide insights on feasible deployment densities, beam management strategies, and necessary capacity extensions. While the framework can be applied to any indoor mmWave networking scenario, our case study focuses on an open office environment for illustrative purposes.

II. INDOOR MMWAVE CHANNEL

It is well known that many aspects of wireless communications, e.g., system design, network topology and performance, are dependent upon an accurate understanding of the channel characteristics. Therefore, channel characteristics at mmWave must be comprehensively studied to allow detailed channel models to be developed. This knowledge will both inform the design of future mmWave communications systems and help predict important performance measures such as the achievable outage probabilities and capacities. In wireless communications channels, the characteristics of the received signal are often characterized in terms of path loss, shadowing and small-scale fading. In what follows, we introduce the κ - μ fading model and provide empirical evidence for its utility and versatility in the context of mmWave communications, in particular for indoor hotspot eMBB applications, which is one of the five test use cases selected in [17].

A. Indoor mmWave Channel Measurements

A number of studies have recently been conducted in [5], [13], [20]–[24], which are key to the provisioning of future 5G services at mmWave frequencies for both indoor and outdoor environments. In most previous mmWave channel studies [22]–[24], the measurements have considered the case where both the transmitter (TX) and receiver (RX) are stationary and mounted on stands. In some of these studies [22], [23], obstructions residing in the optical line-of-sight (LOS) path between the TX and RX are analyzed. However crucially, none of these studies consider scenarios where the TX and/or RX are in close proximity to the human user body. To this end, in this work, we have considered the case where a hypothetical user equipment (UE) (i.e., the TX in our case) is held by the user while imitating different UE operating modes. Furthermore, the user is moving through the environment. This is driven by the need to understand the potential impact of UE operation mode and user mobility on the small-scale fading characteristics, knowledge of which will be essential for determining the localized performance of future user-centric mmWave networks.

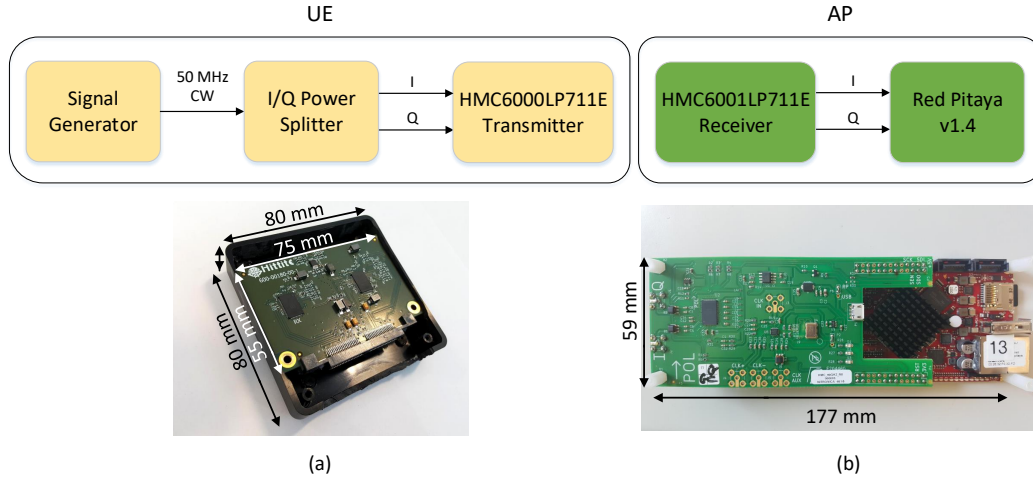

Fig. 2. Hypothetical (a) UE and (b) AP used for the mmWave channel measurements.

1) *Measurement System and Environments:* To emulate a possible indoor hotspot eMBB use case the mmWave channel between a UE and access point (AP) is considered. The hypothetical UE and AP used for the mmWave channel measurements are shown in Fig. 2(a) and (b), respectively. Details of the hypothetical UE and AP can be found in [25]. The channel measurements were conducted within a hallway ($17.38 \text{ m} \times 1.40 \text{ m}$) and an open office area ($10.62 \text{ m} \times 12.23 \text{ m}$) as shown in Fig. 3. Both the hallway and open office environments are located on the 1st floor of the Institute of Electronics, Communications and Information Technology (ECIT) at Queen's University Belfast in the United Kingdom. Both environments featured metal studded dry walls with a metal tiled floor covered with polypropylene-fiber, rubber backed carpet tiles, and metal ceiling with mineral fiber tiles and recessed louvered luminaries suspended 2.70 m above floor level. The open office area contained a number of soft partitions, cabinets, personal computers, chairs and desks. It should be noted that both the hallway and open office environments were unoccupied for the duration of the channel measurements and the AP was placed above a ceiling tile with the antenna boresight oriented towards the floor, i.e., imitating a ceiling-mounted AP.

2) *Usage Cases:* During the measurements, the UE was operated by an adult male of 1.83 m in height and mass 80 kg. A number of different use cases likely to be encountered in everyday scenarios were considered. These were: (1) operating an app, where the user held the UE with his two hands in front of his body; (2) carrying a device I, where the UE was located in the right-front pocket of the user's clothing; (3) carrying a device II, where the user held the UE with his right hand beside his right leg. Herein, and for brevity, we denote the three different

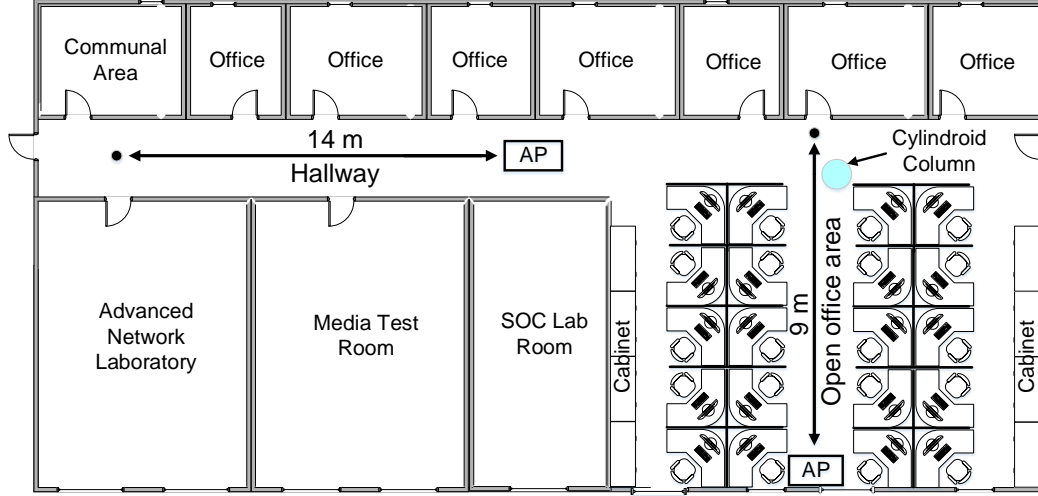

Fig. 3. Indoor hallway and open office environments considered in this study along with annotated user trajectories.

UE usage cases as *app*, *pocket* and *hand* respectively. In this study, we considered two different dynamic channel conditions, namely, (1) *mobile LOS* and (2) *mobile non-LOS (NLOS)*, where the user walked towards and away from the hypothetical AP in a straight line, respectively. It is worth remarking that the NLOS channel conditions occurred when the direct optical path between the UE and AP was obstructed by the user's body, i.e., self-blockage.

To improve the validity and robustness of the parameter estimates obtained in this study, all the measurements were repeated three times. Due to the dissimilar sizes of each environment, the considered walking distances were different. In particular, these were 9 m and 14 m for the open office area and hallway respectively. The average walking speed maintained by the user throughout all of the experiments was approximately 1 m/s.

3) *Path Loss*: The path loss is a measure of the signal attenuation between the transmitter and receiver as a function of the separation distance and can be expressed as [26]

$$P [\text{dB}] = P_0 [\text{dB}] + 10\alpha \log_{10} (d/d_0), \quad (1)$$

where P_0 represents the path loss at the reference distance d_0 , α is the path loss exponent which indicates the rate at which the path loss increases with distance and d is the separation distance between the transmitter and receiver. To obtain estimates for P_0 and α , we first removed the maximum effective isotropic radiated power (EIRP) and gain at the receiver from the raw signal power received by the AP and then performed linear regression. To enable this, the elapsed

time was first converted into a distance using the test user's velocity. The reference distance, which should be in far field region of the antenna, was chosen to be 1 m for all environments. The mean values of the parameter estimates for P_0 and α averaged over all the trials for all of the considered cases are given in Table I along with the body blockage, which is defined as the difference between the path loss at the reference distance (i.e., P_0) for the LOS and NLOS conditions². The path loss exponents for the LOS scenarios were found to be smaller than that associated with isotropic radiation in free space ($\alpha = 2$). This was possibly due to the waveguide effect which can often be present within indoor environments [28]. As anticipated, for both the hallway and office environments, the P_0 values for the NLOS were greater than those for the LOS due to the shadowing effects caused by the test user's body. When considering the values of the body blockage, it was observed that the hand case had a smaller body blockage compared to those for the app and pocket cases. This confirms the intuition that the UE to ceiling-mounted AP channel is less susceptible to body blockage when the user is carrying the UE further away from the body, which is the case with the hand scenario.

4) *Small-Scale Fading*: The κ - μ distribution has been proposed as a generalized statistical model, which may be used to characterize the random variation of the received signal caused by multipath fading [29]. The probability density function (PDF) of the signal envelope, H , in a κ - μ fading channel can be expressed as

$$f_H(h) = \frac{2\mu(\kappa + 1)^{\frac{\mu+1}{2}} h^\mu}{\kappa^{\frac{\mu-1}{2}} \exp(\mu\kappa) \Omega^{\frac{\mu+1}{2}}} \exp\left(\frac{-\mu(\kappa + 1)h^2}{\Omega}\right) I_{\mu-1}\left(2\mu\sqrt{\kappa(\kappa + 1)}\frac{h}{\sqrt{\Omega}}\right) \quad (2)$$

where $I_v(\cdot)$ represents the modified Bessel function of the first kind with order v . In terms of its physical interpretation, κ is defined as the ratio between the total power in the dominant signal components and the total power in the scattered signal components, μ is the number of multipath clusters and Ω is the mean signal power given by $\Omega = \mathbb{E}[H^2]$.

The small-scale fading was extracted by removing *both* the path loss and large-scale fading³ from the channel data before transforming the data to its linear amplitude. The parameter estimates for the κ - μ fading model were obtained using a non-linear least squares routine.

²Although we define the body blockage as the difference between the path loss at the reference distance for the LOS and NLOS conditions in this paper, the human body blockage loss is also presented in [27] using the double knife-edge diffraction.

³The large-scale fading was extracted from the received signal power by first removing the estimated path loss using the parameters given in Table I. The resulting dataset was then averaged using a moving window of 100 channel samples (equivalent to a distance of 10 wavelengths).

TABLE I
AVERAGE PARAMETER ESTIMATES FOR THE PATH LOSS MODEL AND κ - μ FADING MODEL FOR ALL OF THE CASES.

Environ- ment	Use Case	LOS					NLOS					Body Blockage
		$\bar{\alpha}$	$\bar{P}_0[\text{dB}]$	$\bar{\kappa}$	$\bar{\mu}$	$\bar{\Omega}$	$\bar{\alpha}$	$\bar{P}_0[\text{dB}]$	$\bar{\kappa}$	$\bar{\mu}$	$\bar{\Omega}$	
Hallway	app	1.92	78.31	2.80	0.77	1.16	1.93	95.39	0.67	0.96	1.25	17.09 dB
	pocket	1.92	82.55	2.64	0.78	1.17	1.95	95.60	0.47	1.02	1.24	13.05 dB
	hand	1.93	90.42	1.89	0.88	1.18	1.94	97.49	0.89	0.99	1.22	7.06 dB
Office	app	2.58	81.31	1.14	1.00	1.21	1.03	101.41	0.48	1.00	1.26	20.09 dB
	pocket	1.38	92.32	1.46	0.91	1.21	1.01	102.11	0.46	1.00	1.26	9.79 dB
	hand	1.52	95.74	1.24	0.93	1.21	1.38	101.83	0.50	1.04	1.24	6.09 dB

Table I provides the mean parameter estimates for the κ - μ fading model averaged over all three trials for each of the UE to AP channels.

Our first observation is that the obtained results provide evidence for the correctness of our methodology. For all of the LOS scenarios and environments, the κ parameters were found to be greater than unity ($\kappa > 1$), indicating the presence of a strong dominant signal component. In contrast, for the NLOS scenarios (i.e., when the direct signal path was blocked by user's body), the κ parameters were smaller than unity ($\kappa < 1$), indicating the absence of a dominant signal contribution. Additionally, for the NLOS scenarios, the κ parameters obtained for the hand case were slightly greater than those for the app and pocket cases, suggesting that the UE to ceiling-mounted AP link for the hand is less impacted by the human body blockage. The μ parameters for the LOS scenarios were slightly smaller than those obtained for the NLOS scenarios. This suggests that the signal fluctuation observed in the LOS scenarios is less impacted by multipath clustering compared to that experienced in NLOS. As an example of the fits obtained, Fig. 4 presents the empirical PDFs of the small-scale fading alongside the κ - μ PDFs for all of the UE usage cases while the operator walked towards the hypothetical AP in the hallway environment. It is clear that the κ - μ fading model is in excellent agreement with the measurement data.

To ascertain the most probable model between the κ - μ and Rayleigh distributions for characterizing the small-scale fading observed in the UE-to-AP channels, the Akaike Information Criterion (AIC) was employed. More specifically, the second-order AIC (AIC_c) was used in a similar manner to the analysis employed in [30], such that

$$AIC_C = -2 \ln(l(\theta|\text{data})) + 2M + \frac{2M(M+1)}{n-M-1} \quad (3)$$

where $\ln(l(\theta|\text{data}))$ is the value of the maximized log-likelihood for the unknown parameter θ

Fig. 4. Empirical (bars) and theoretical (continuous lines) PDFs of the small-scale fading observed in the hallway environment for the LOS scenario with (a) app, (b) pocket and (c) hand cases.

TABLE II
AIC_c RANK FOR ALL OF THE CONSIDERED UE-TO-AP CHANNEL MEASUREMENT DATA.

Environment	Use Case	LOS		NLOS	
		κ - μ	Rayleigh	κ - μ	Rayleigh
Hallway	app	1	2	1	2
	pocket	1	2	1	2
	hand	1	2	1	2
Office	app	1	2	1	2
	pocket	1	2	1	2
	hand	1	2	1	2

of the model given the data, M is the number of estimated parameters available in the model, and n is the sample size. It should be noted that the lower the AIC_c value, the more likely the candidate model was to have generated the data. As shown in Table II, the κ - μ and Rayleigh fading models were ranked according to their AIC_c. It is clear that the κ - μ distribution was selected as the best model for all of the considered cases, suggesting that the added complexity (i.e., additional parameters) in the κ - μ model are worthwhile.

III. SYSTEM-LEVEL MODELLING AND PERFORMANCE EVALUATION

Indoor mmWave networks will be characterised by much shorter distances between access points and users as well as deployments that will be confined to closed areas and made independent from outdoor deployments due to weak out-in penetration [31]. Furthermore, in Section II we reported that in the presence of a human user body the indoor mmWave channel becomes highly complex with a mix of large- and small-scale fading effects. Understanding how the basic network parameters such as access point density, antenna beamwidth, and serving distance

will impact network performance in these conditions requires new and extensive system-level modelling approaches.

In this section we develop an analytical framework and quantify the performance of indoor mmWave networks. Our framework bridges the statistical channel models obtained from measurement campaigns, described in Section II, with stochastic network geometry, which reflects the fact that at any given point in time the set of user locations and/or transmitter directionalities may be considered random. Our framework yields analytical expressions describing the distribution of the signal-to-interference and noise ratio (SINR) in a generic indoor mmWave network. While the obtained expressions are too complex to be amenable to intuition, they allow us to cross-validate Monte Carlo simulations and, in some cases, generate numerical results that would otherwise be difficult to obtain using simulations only. Ultimately, we explore the relationship between basic network parameters, channel scenarios and network performance indicators: coverage, Area Traffic Capacity (ATC), and Experienced Data Rate (EDR), which we define in Section III-B. Moreover, we look critically at some of our assumptions by considering how network performance changes with serving distance and blockage conditions.

Most work to date on system-level evaluations for mmWave networking are focused on large-scale outdoor areas, e.g., [32]–[34]. Indoor area mmWave network analysis has received much less attention, with some earlier works considering device-to-device applications [35], [36], and more recent works addressing hotspot deployments [37]–[40]. While building on the relevant literature, our work presented in this section goes beyond it in two important ways. First, building on our work in [41], we offer analysis based on the experimentally-validated κ - μ fading model, which allows us to consider the impact that different device usage scenarios have on network performance. Then, the network setup we consider is aligned with network setups recommended for system-level evaluation of mobile mmWave systems [11], [42]. For these we provide analytical expressions describing network performance which, for special cases, can be reduced to closed-form expressions.

A. System Model

Network Geometry: We consider a network with a finite number of transmitters $\Phi = \{x_0, x_1, \dots, x_{n_{\text{TX}}-1}\} \subset \mathcal{W}$, whose locations are uniformly distributed over a finite arbitrary area $\mathcal{W} \subset \mathbb{R}^2$. Our analysis takes the perspective of the *reference receiver*, which is an arbitrary point in \mathcal{W} at distance ρ_0 from the center of mass of \mathcal{W} . Since we are interested in analyzing feasible networks, we consider

\mathcal{W} to always contain the reference receiver and the transmitter serving that reference receiver (the *serving transmitter*), which, in our notation, is always indexed as 0. On the horizontal plane, the reference receiver and the serving transmitter are a distance $r_0 \geq 0$ apart. We will refer to the wireless link between the reference receiver and its transmitter as the *reference link*. Transmissions from remaining $n'_{\text{TX}} = n_{\text{TX}} - 1$ transmitters will be treated as interference to the reference link. We assume that all transmitters are located at height h_{TX} above the ground, with the reference receiver operating at height h_{RX} .

Directionality Gain: All transmitters and receivers utilize directional transmission and reception. We assume the transmitter (receiver) antenna gain is calculated based on the cone-bulb model [37]. In this model the main-lobe gain G_{TX} is a function of the beamwidth ω_{TX} , normalized over the whole spherical surface:

$$G_{\text{TX}} \frac{1 - \cos(\omega_{\text{TX}}/2)}{2} - g_{\text{TX}} \frac{1 + \cos(\omega_{\text{TX}}/2)}{2} = 1, \quad (4)$$

where g_{TX} is the side-lobe gain. Correspondingly, we will use G_{RX} , g_{RX} , and ω_{RX} to refer to the main-lobe gain, side-lobe gain, and beamwidth of the receiver antenna. Usage of the cone-bulb model and the main-lobe beamwidth as our parameter abstracts our analysis from the choice of the antenna system, and makes our results applicable to scenarios with fixed directional antennas. This could be the case, for example, in lecture halls or open offices where users remain static. Conversion between beamwidth, antenna gain, and number of antenna elements for various types of antennas can be found in [43]. Let us note that the cone-bulb model is also a risk-averse choice as it leads to underestimation of coverage results [44].

Then the directionality gain is the product of transmitter and receiver antenna gains, which depend on the beam alignment between the two [45]. Using the convention that the alignment gain between the receiver and a transmitter is random, we can represent it as a four-dimensional categorical random variable G_i , with $i \in \{0, \dots, n_{\text{TX}} - 1\}$. This random variable maps from the space of all possible alignments between the transmitter i and the reference receiver to the space of alignment gains \mathcal{G} that is formed as a product of the transmitter and receiver antenna gains, with the corresponding probability mass function $p_{g_i} = \mathbb{P}(G_i = g_i)$. In practice the alignment gain from the serving transmitter is maintained stable by beam management operations, which corresponds to conditioning $G_0 = g_0$, where G_0 is the alignment gain on the reference link and g_0 a constant.

Blockage: In our framework, link blockage arises from self-blockage, i.e., blockage of the LOS signal path between the receiver and the transmitter by the human user. The severity of this blockage will depend on the usage scenarios defined in Section II: *app* with a device held in front of the user, *pocket* with a device held in the front pocket, *hand* with a device carried in the hand. For each scenario, we consider fixed blockage on the reference link⁴ and probabilistic blockage on all other links. Consequently, blockage is a Bernoulli random variable, with the success probability p_{LOS} and $p_{\text{NLOS}} = 1 - p_{\text{LOS}}$, where the latter is referred to as the blockage probability. Here we opt for a model where p_{LOS} (or, indeed, p_{NLOS}) is simply a system parameter that reflects the frequency of link blockages. Furthermore, we assume that each transmission link experiences blockages independently of all other links. Numerical evaluations in [40] show that this independence assumption results in negligible differences to the blockage probability.

Propagation Model: In our system-level modelling, we use the model as proposed in Section II, but to capture the bifurcation of its parameters (due to link blockage) we adopt the following notation for the pathloss and power fading:

$$l_t(r_i) = \gamma_t r_i^{\alpha_t}, \quad f_{H_{i,t}}(h) = \frac{\theta_{1,t}^{(\mu_t+1)/2}}{\theta_{2,t}^{(\mu_t-1)/2}} h^{(\mu_t-1)/2} \exp(-\theta_{1,t}h - \theta_{2,t}) I_{\mu_t-1} \left(2\sqrt{\theta_{1,t}\theta_{2,t}h} \right), \quad (5)$$

where r_i , with $i \in \{0, \dots, n_{\text{TX}} - 1\}$, is the distance to the i -th transmitter, $t \in \{\text{LOS}, \text{NLOS}\}$ blockage state, $\gamma_{i,t}$ attenuation at the reference distance, α_t pathloss exponent, $\theta_{1,t} = \frac{\mu_t(1+\kappa_t)}{\sqrt{\Omega_t}}$, and $\theta_{2,t} = \mu_t\kappa_t$. Scattering and diffraction via static objects, such as inner walls or office furniture, are not explicitly modelled, yet their impact is included in the parameter values given in Table I.

Signal-to-Interference-and-Noise Ratio: Given a transmitter at x_i and blockage state $t \in \{\text{LOS}, \text{NLOS}\}$, the instantaneous power received at the reference receiver located in $y_0 \in \mathcal{W}$ is:

$$S_{i,t} = G_i H_{i,t} l_t(r_i), \quad (6)$$

where $r_i = \sqrt{\|x_i - y_0\|^2 + (h_{\text{TX}} - h_{\text{RX}})^2}$ is the distance between the reference receiver and transmitter i , $H_{i,t}$ is the blockage-dependent power fading, and $l_t(r_i)$ is the blockage-dependent path attenuation. Then the SINR, under blockage state t on the serving channel is given by

$$\text{SINR} = \frac{S_{0,t}}{I + \tau^{-1}}, \quad (7)$$

⁴This pertains to the worst/best case analysis.

where $S_{0,t}$ is the instantaneous power received from the serving transmitter, $I = \sum_{i=1}^{n'_{\text{TX}}} S_i$ is the interference power, with $S_i = \mathbb{E}_{V_i}[S_{i,V_i}]$ being the received signal power from transmitter i averaged over possible blockage states V_i on link i , and τ is the signal-noise ratio⁵.

B. Network Performance Characterization

We utilize three key performance indicators recommended by the 3GPP [11]: coverage, ATC, and EDR. Broadly speaking, the first represents the coverage achievable in our network, the second provides us with information on the expected user throughput, and the third represents the throughput achievable by users that experience poor channel conditions.

Coverage: We represent the coverage as the probability that the SINR is greater than some pre-defined coverage threshold ζ , which is equivalent to finding the complementary cumulative distribution function (CCDF) of the SINR:

$$\mathbb{P}(\text{SINR} > \zeta) = F_{\text{SINR}}^c(\zeta). \quad (8)$$

Area traffic capacity: ATC is a measure of the total traffic a network can serve per unit area (in Gbit/s/m²), which can be calculated as:

$$C_{\text{area}} = \lambda \times \text{bw} \times \text{SE} \quad (9)$$

where λ is the transmitter density, bw is the transmission bandwidth, and SE is the spectral efficiency. The spectral efficiency is the average data rate per unit of spectrum and per cell, which can be expressed⁶ in terms of the CCDF of the SINR as:

$$\text{SE} = \int_0^\infty \mathbb{P}(\log(1 + \text{SINR}) > r) dr = \int_0^\infty F_{\text{SINR}}^c(2^r - 1) dr. \quad (10)$$

Experienced data rate: We define the EDR as the 5th percentile of the user throughput distribution, which can also be found numerically following the approach proposed in [46]:

$$q_R(\beta = 0.05) = \underset{u}{\operatorname{argmin}} \left\{ u + \frac{1}{1 - \beta} \int_u^\infty F_{\text{SINR}}^c(2^{r/\text{bw}} - 1) dr \right\}. \quad (11)$$

⁵For simplicity, we assume the transmit power is identical across all transmitters.

⁶Noticing that the spectral efficiency is an expectation over a positive random variable $\log(1 + \text{SINR})$.

C. Analytical Results

In the following we provide our main analytical results. We start with the distribution of the received power in Lemma 1, which we subsequently use to characterize the CCDF of the SINR for a mmWave network distributed over an arbitrary finite area in Lemma 2. Finally, we specialize this result to the case of a network distributed over a disk in Corollary 1.

Lemma 1 (Received Power Statistics): Given transmitter i at distance r_i , directionality gain g_i , and blockage state t , the CCDF of $S_{i,t}$ can be expressed as:

$$\mathbb{P}(S_{i,t} > x) = \exp(-\theta_{2,t}) \sum_{l=0}^{\infty} \frac{\theta_{2,t}^l}{l!} \sum_{n=0}^{l+\mu_t-1} \frac{1}{n!} \left(\frac{\theta_{1,t}x}{\vartheta_{i,t}} \right)^n \exp\left(-\left(\frac{\theta_{1,t}}{\vartheta_{i,t}}\right)x\right), \quad (12)$$

where $\theta_{1,t}$ and $\vartheta_{i,t}$ are provided in (5) and (29), respectively.

Proof: The above formula relies on a simple re-formulation of the PDF in (5), and the subsequent calculation of the resulting cumulative distribution function (CDF), which is presented in Appendix A. ■

Remark 1 (Other representation of Lemma 1): In Lemma 1 we define the received power distribution using infinite series representation to facilitate further derivations of the SINR. However, the distribution in question can also be represented in closed-form, as shown in [29], utilizing the generalized Marcum-Q function.

Lemma 2 (Distribution of SINR for an Arbitrary Area): Given the distance to the serving transmitter r_0 , its directionality gain g_0 and LOS blockage state t , the conditional CCDF of the SINR is given by

$$\begin{aligned} \mathbb{P}(\text{SINR} > \zeta | G_0 = g_0, R_0 = r_0, T_0 = t) = \\ \exp\left(-\theta_{2,t} - \frac{\zeta \theta_{1,t}}{\vartheta_{0,t}\tau}\right) \sum_{l=0}^{\infty} \frac{\theta_{2,t}^l}{l!} \sum_{n=0}^{l+\mu_t-1} \frac{1}{n!} \left(\frac{\zeta \theta_{1,t}}{\vartheta_{0,t}\tau} \right)^n \sum_{k=0}^n \binom{n}{k} \tau^k \\ \sum_{k_1+k_2+\dots+k_{n_{\text{TX}}}=k} \binom{k}{k_1, k_2, \dots, k_{n_{\text{TX}}}} \prod_{1 \leq i \leq n_{\text{TX}}} \sum_{v \in \{\text{LOS}, \text{NLOS}\}} p_v \sum_{g \in \mathcal{G}} p_g(\mu_v)_{k_i} \theta_{1,v}^{\mu_v} g^{k_i} \exp(-\theta_{2,v}) \mathfrak{Z}_{k_i}, \\ \text{where } \mathfrak{Z}_{k_i} = \mathbb{E}_R \left[\left(\frac{l_v^{k_i}(R)}{\left(\frac{\zeta \theta_{1,t}}{\vartheta_{0,t}} g l_v(R) + \theta_{1,v} \right)^{k_i + \mu_v}} {}_1F_1 \left(k_i + \mu_v; \mu_v; \frac{\theta_{1,v} \theta_{2,v}}{\frac{\zeta \theta_{1,t}}{\vartheta_{0,t}} g l_v(R) + \theta_{1,v}} \right) \right) \right] \end{aligned} \quad (13)$$

and $\vartheta_{0,t} = g_0 l_t(r_0)$, and ${}_1F_1(; ;)$ is the confluent hypergeometric function.

Proof: The proof is provided in Appendix B. ■

In our numerical evaluations we will consider the case of \mathcal{W} being a disk of fixed radius ρ around the origin. In this case the expectation in (13) is taken with respect to the distance between the reference receiver and a uniform point located within \mathcal{W} with the PDF [47]:

$$f_R(r) = \frac{1}{\pi\rho^2} \begin{cases} 2\pi r, & 0 \leq r \leq \rho - \rho_0 \\ 2r \arccos \frac{r^2 + \rho_0^2 - \rho^2}{2\rho_0 r}, & \rho - \rho_0 \leq r \leq \rho + \rho_0. \end{cases} \quad (14)$$

In the case when the reference receiver is at the center of \mathcal{W} , we get the closed-form result stated in Corollary 1.

Remark 2 (Usability of Lemma 2): While the formula in (13) yields no intuition on mmWave network designs, in certain cases it is more computationally effective than the corresponding Monte Carlo simulations, and can be easily modified to account for:

- Arbitrarily-sized areas⁷ with arbitrary reference receiver locations (to test for potential boundary effects).
- Arbitrary pathloss exponents, as given in Table I.
- Other random blockage or antenna gain models.
- Deterministic deployments, in which case the expectation in (13) should be replaced with a summation over a set of pre-defined distances.

Corollary 1 (Specializing Lemma 2 to the case of a receiver located in the center of a disk): Given the distance to the serving transmitter r_0 , its directionality gain g_0 and LOS blockage state t , we get that \mathfrak{Z}_{k_i} in Lemma 2 can be represented using the following closed-form expression:

$$\mathfrak{Z}_{k_i} = \frac{2\gamma_v^{k_i} y^{2-k_i\alpha_v}}{\rho^2 \theta_{1,v}^{k_i+\mu_v} (2-k_i\alpha_v)} \Psi_1(k_i + \mu_v, k_i - 2/\alpha_v, \mu_v, k_i - 2/\alpha_v + 1; \theta_{2,v}, -\frac{\zeta_{\theta_{1,t}}}{\vartheta_{0,t}\theta_{1,v}} g\gamma_v y^{-\alpha_v}) \Big|_{y=\sqrt{\rho^2+h^2}}, \quad (15)$$

where Ψ_1 is the Humbert series, which can also be denoted using the Appell series notation as $F_2(a; b, -; c, c'; x, y)$.

Proof: The proof is provided in Appendix C. ■

Remark 3 (Computationally-Efficient Evaluation of Lemma 2): Due to the exponentially growing number of combinations that involve products of hypergeometric series, the expression in

⁷Distance distributions corresponding to a variety of useful geometric shapes can be found in [48].

Lemma 2 even for a relatively small number of transmitters may become cumbersome to evaluate numerically. In order to speed up the numerical evaluations one can pre-compute the indices and the individual terms of the multinomial expansion, and store them into two separate matrices. During the evaluation of the expression in Lemma 2 the elements of the indices matrix can be used to address the elements of the terms matrix, similarly to the approach proposed in [49]. Finally, calculating expectation from the definition in (10) quickly becomes computationally challenging, in which case one may derive analytical representation to this expectation using the approach proposed in [50].

D. Numerical Evaluations

Here we numerically evaluate system-level implications of indoor mmWave deployments, under a variety of body blockage scenarios as described in Section II. In our evaluations, we set the parameters for network geometry and configuration following the Indoor Hotspot eMBB performance evaluation setup recommended by the 3GPP and International Telecommunications Union – Radiocommunication (ITU-R)⁸, in [11] and [17] respectively. For the propagation and channel settings, we consider the models and values coming from measurements presented in Section II. We illustrate coverage results based on numerical evaluations of the obtained analytical formulas and Monte Carlo simulations⁹, while the ATC and EDR results come from Monte Carlo simulations only due to high computational footprint of the exact averaging formulas¹⁰.

1) Evaluation Setup: The considered area has a shape of a disk of radius $\rho = 12$ m, which roughly corresponds to the size of the area considered by the 3GPP. There are n'_{TX} interfering transmitters, located independently and uniformly within the area, and one transmitter that is also the serving transmitter located a distance r_0 apart from the reference receiver in random direction. An example realization of our setup is illustrated in Fig. 5.

The deployment is laid out over one floor. According to our measurement setup in Section II each transmitter is at a height of $h_{\text{TX}} = 3$ m, while the reference receiver is at a height $h_{\text{RX}} = 1.5$ m. Effectively the reference receiver always stays at a distance greater than the reference

⁸The recommendations follow each other closely, with the ITU-R document offering more detailed assumptions, e.g., about the ceiling or human user heights assumed.

⁹Generally speaking, we will use solid lines to plot numerical values coming from analytical expressions and marks to plot the ones coming from Monte Carlo simulations.

¹⁰We should note that given the number of random variables in our system accurate evaluation requires large number of samples for numerical evaluations.

Fig. 5. Snapshot of the indoor mmWave hotspot layout with five transmitters. The reference receiver location is marked with a rectangle and the transmitter locations are the small circles. The direction of transmissions for all the transmitters is illustrated as rotation of the 2D- projection of the cone bulb antenna gain model in (4).

distance of 1 m from the transmitter. We assume that directionalities of beams produced by n'_{TX} interfering transmitters are uniform and independent across space, and the transmitter/receiver antenna side-lobe gain is $g_{\text{TX}} = g_{\text{RX}} = -25$ dBm, while the main-lobe gain is calculated, for a given beamwidth, using (4). The receiver beamwidth is $\omega_{\text{RX}} = 30^\circ$ and, unless otherwise stated, $n_{\text{TX}} = 12$, $\omega_{\text{TX}} = 30^\circ$, and $r_0 = 1$ m. We assume that our network uses 200 MHz of bandwidth (corresponding to the bandwidth of a component carrier in 5G [51]) for full buffer, downlink transmissions, at a transmit power of 23 dBm and the noise figure of 7 dB.

Assuming channel reciprocity¹¹, we use the parameter values given in Table I while rounding the μ parameters to the nearest integer value. We take this step to improve the analytical tractability of our derivations and results (see Appendix B) meaning that they can be readily incorporated into other communications performance analyses beyond this study. We would like to highlight that this rounding of the μ parameter has negligible effect on the observed network performance and is more amenable to the physical interpretation of the results, as the μ parameter quantifies the number of clusters of scattered multipath.

In the following we will first look at the network design implications coming from our model and consider the impact that the number of transmitters and their antenna directionality have on the system performance. We perform our numerical analysis for an idealistic case, assuming

¹¹As stated in the Introduction, so far 5G NR mmWave technology has been standardized to operate in TDD mode only [52].

that our serving transmitter is at a horizontal distance of 1 m away from the reference receiver (which, as we will show later, allows us to meet ATC and EDR targets for most of the analysed scenarios), with its main beam being fully aligned with the receiver beam, and an LOS channel between the two. Subsequently, we will re-visit these assumptions and consider how network performance changes with increased distance to the serving transmitter and when the reference link is in NLOS state.

2) *Network performance*: First let us consider how the results we obtained compare to the performance requirements imposed on the 3GPP Indoor Hotspot scenario. Following the chairman of the 3GPP system architecture group [53], these include 1 Gbit/s of EDR, and 15 Tbps/km² of ATC, both in the downlink direction. As we can see from Fig. 6, whether or not we meet the performance targets is highly dependent on the usage scenario. Broadly speaking, scenarios where the user device is held further away from the user body achieve the ATC target with 4 transmitters in a given area and maintain values higher than target EDR for all of the considered network densities. The reason for this is low path attenuation at the reference distance. For that same reason Hallway pocket scenario meets target requirements. The other scenarios require double the number of transmitters to achieve the same performance, but, critically, do not offer target EDR.

Looking at Fig. 6(a) we see that the increasing number of transmitters leads to linear increase in ATC, which, given the expression in (9), comes from the linear increases in the number of available infrastructure per unit area. Due to relatively narrow beams that we use, $\omega_{TX} = 30^\circ$, this densification does not lead to increase in interference, which can be confirmed by observing almost flat EDR curves in Fig. 6(b) (which illustrates the performance of users that would suffer the most if any increase in interference occurred). The coverage plots in Fig. 6(c) show the exact same story providing us with almost flat lines for each of the considered scenarios. In conclusion, we see that for the selected network setup our network operates in the noise-limited regime for all of the usage scenarios with the exception of the *Hallway app* that is characterized by low reference distance path attenuation.

Another way to bring the data rates up would require that we increase the antenna gains by using narrower beams, either on the transmitter (as shown in Fig. 7), or the receiver side. Beamwidth has a much more critical impact on both the ATC and EDR. In Fig. 7(b), we can see that for some of the scenarios the EDR drops to values below what, for example, an average Long Term Evolution (LTE) user would experience. In order to ensure that users under all usage

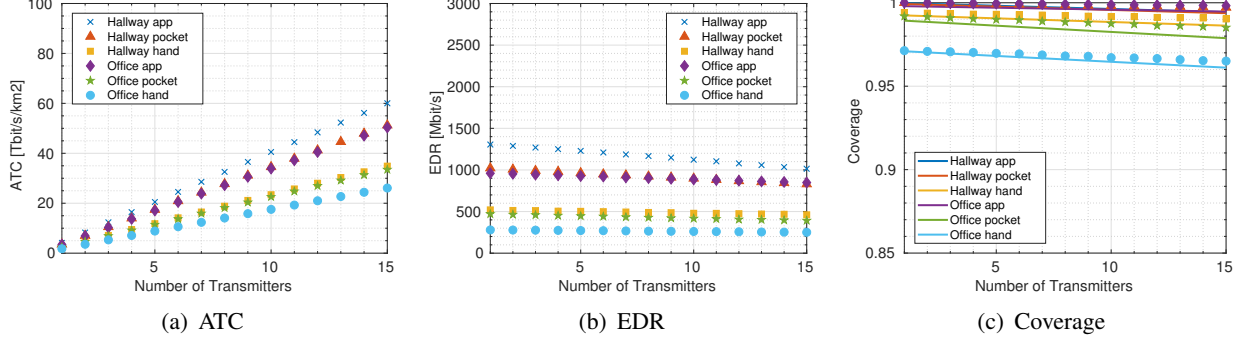

Fig. 6. Impact of the number of transmitters n_{TX} . Where $n_{TX} = 1$ represents the scenario with a single serving transmitter and no other transmitters within a given area. Other network settings are: $\omega_{TX} = 30^\circ$, $r_0 = 1$ m, and $p_{LOS} = .5$.

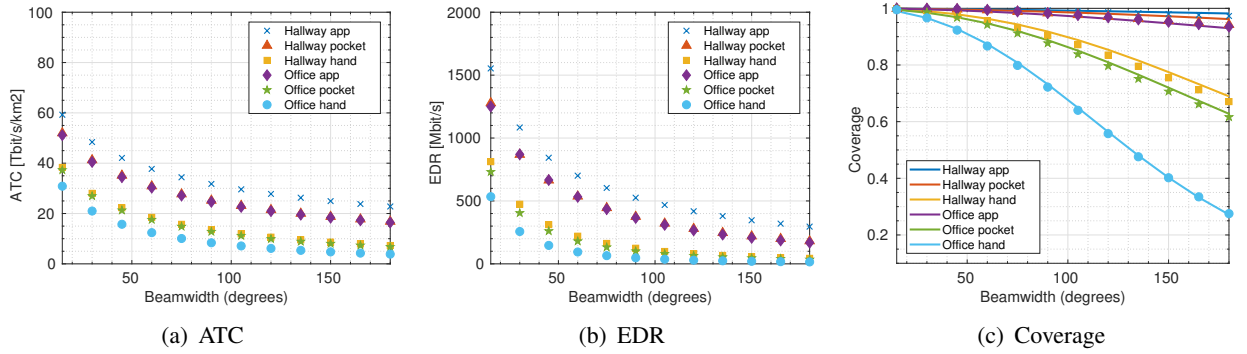

Fig. 7. Impact of the transmitter antenna main-lobe width ω_{TX} . The antenna gain scales with ω_{TX} according to (4). Other network settings $n_{TX} = 12$, $r_0 = 1$ m, and $p_{LOS} = .5$.

scenarios enjoy target EDR would require that we use transmitter beamwidths far below our default configuration of 30° . Wider beams produce significant interference which greatly reduces the performance of the worst-off users for the three scenarios with high reference distance path attenuation. However, in the other three scenarios while the performance reduces it does so only to a lesser degree and ATC stays above the target performance for all beamwidths considered.

When it comes to coverage (see Fig. 6(c) and Fig. 7(c)) we should remark that—as one would expect—increasing the number of transmitters deteriorates coverage. In Fig. 6(c), coverage degrades linearly with the number of transmitters, albeit at a negligibly small rate. This is good news as it means that the resulting interference may be low enough to not warrant the need for interference coordination, at least as long as directionalities of transmissions are independent across space, an observation also made for large-scale, outdoor mmWave networks [54]. The choice of the beamwidth has a more critical impact on the coverage performance, in Fig. 7(c). If the coverage is to be kept at (or above) 90% mark for all of the scenarios, it is necessary that the

transmitter beamwidth stays at (or below) roughly 60° , as wider beams may produce unmitigated interference. Interestingly, when beams of 50° or more are used, we start seeing differences in coverage between the scenarios. Similarly to changes in ATC and EDR performance this can be explained by high discrepancy in the path attenuation at the reference distance between the usage scenarios.

3) *Network performance under design imperfections:* In Fig. 8 we consider the horizontal distance to the serving transmitter. In practical cases a particular cell will serve a particular user. This means the serving distance may not depend on the density of transmitters or receivers. In Fig. 8 we see that all our performance characteristics degrade with the serving distance. The serving distance is especially critical for the coverage, as in four of our usage cases the coverage goes below the 90% mark at roughly 5 m horizontal distance already. Interestingly this does not affect the ATC performance which stays at relatively high values even at longer serving distances. Yet, the performance of worst-off users becomes highly volatile to change in their distance to the serving transmitter, and all of our scenarios fall below the 1 Gbit/s target beyond the horizontal distance of 2 m.

We are also interested in testing how the performance changes when the reference link is in blockage state caused by the user body. In Fig. 9 we see – following intuition – that LOS blockage leads to performance degradation. While the coverage is affected only in a minor way, for each of the scenarios network performance, interpreted as ATC, drops below the performance targets, in the cases where body blockage is high (Hallway app, Hallway pocket, and Office app) dropping by as much as 70%. But more critically, the 5th percentile user throughput becomes only a small fraction of the LOS case. This is an important observation that motivates work into blockage mitigation strategies: [55]–[57]. In our studies we also considered the impact of blockage probability. However, for the setup we used to evaluate our system, the disparity between LOS and NLOS channels on the interfering links was not strong enough to yield any significant differences in performance. We can conclude that while body blockage does indeed introduce significant attenuation to interfering links (see body blockage values in Table I), in a well-designed network with the carefully chosen beamwidths and a reasonable number of transmitters it should not affect network performance.

Since beam management is also a fundamental aspect to consider in mmWave systems [58], in our numerical evaluations we also considered the impact of beam misalignments. Given our system setup, we have observed that any misalignment between transmitter and receiver beams

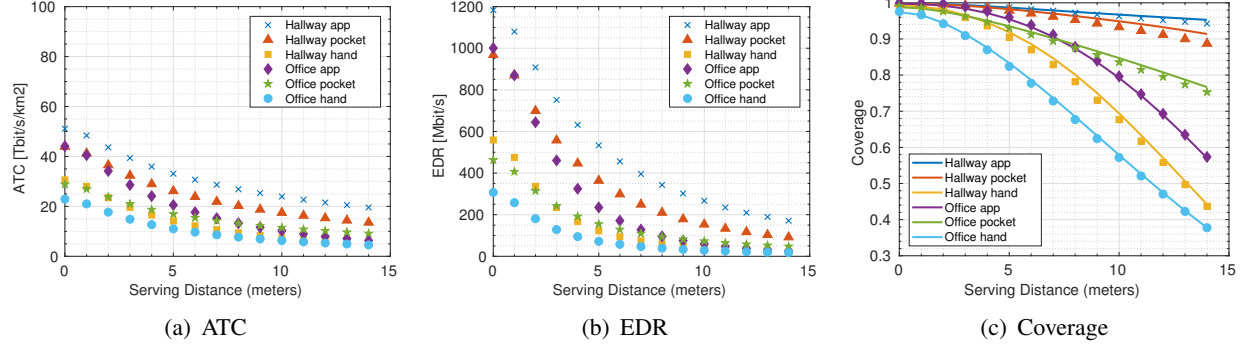

Fig. 8. Impact of the serving distance. Other network settings $n_{TX} = 11$, $\omega_{TX} = 30^\circ$, and $p_{LOS} = .5$.

Fig. 9. Impact of the reference link blockage. Other network settings $n_{TX} = 11$, $\omega_{TX} = 30^\circ$, $r_0 = 1$ m, and $p_{LOS} = .5$.

substantially throttles any communication links between the two, reducing coverage to almost zero. While this result motivates strong need for accurate beam alignment procedures, such as [59], it is also based on a pessimistic antenna pattern model that incorporates sharp degradation in performance in case of any misalignments. In reality misalignments, while still severe in their impact, should lead to lesser performance degradation [60], which would require further studies.

IV. DEPLOYMENT ANALYSIS

Section Section III has addressed system-level modeling and performance evaluation. These tasks are critical to understanding the basic factors that will impact the performance of mmWave deployments across a variety of scenarios. They help us to answer questions about the impact of factors such as base station density, antenna beamwidth, and serving distance on various measures of performance. Nevertheless, after examining these results, actual deployment planning for specific environments remains a challenge in mmWave systems.

In a particular environment, deployment is constrained first by the set of possible AP locations. Then, it is necessary for deployment to consider many of the same factors considered in the analysis in Section III. Namely, issues such as beamwidth and planned serving distance must be considered. In addition, we saw in the last section that whether a link is LOS or NLOS has a significant impact on system performance. For a particular deployment, the issue of LOS vs. NLOS will depend on the location of the APs, user device orientation, as well as orientations of all human bodies in the considered space, including that of the device user.

In this section, we discuss efficient schemes for AP deployment and beam steering in mmWave networks. In particular, given a set of possible AP locations, we setup a stochastic optimization problem to determine the best set of AP locations, as well as the best directions to aim the APs' beams in order to meet coverage requirements while minimizing the deployment cost. We use a stochastic optimization problem to model the fact that the set of user locations at any given time is uncertain, but can be modeled as the realization of a point process. For the purposes of this paper, we step beyond the recent work on mmWave AP deployment by assuming that each AP generates multiple, fixed beams; dynamic beam management is left for future work.

There have been some recent works on AP deployment in mmWave networks, such as [61]–[64]. However, these works neither consider the beam steering problem nor account for the uncertainty in user locations. In [61], the authors proposed an automated scheme for placing mmWave APs and gathering their line-of-sight coverage statistics, to help model small-cell mmWave access networks. Considering the deafness and blockage problems in mmWave networks, in [62], [63] the authors proposed distributed schemes for association and relaying that improve network throughput. In another AP deployment scheme, [64], the authors assumed that APs always direct their beams in one fixed direction and considered a fixed set of UEs with static locations. In contrast, we assume fixed beam directions, but we assume that each access point can generate multiple beams.

Considering uncertainty in the availability of mmWave links between AP and UEs, combined with user location uncertainty, in this section we describe a chance-constrained stochastic programming (CCSP) [65] framework for joint AP deployment and beam steering in mmWave networks, called DBmWave. CCSP has been recently used to model several resource allocation problems in uncertain networks [66]–[68]. DBmWave aims at minimizing the required number of mmWave APs to achieve a minimum *network-wide* coverage probability of β , which represents the requested Quality of Service (QoS) level. The *network-wide* coverage probability constraint

formulated in this paper is in contrast to the *per-user* coverage probability constraint formulated in [64]. Instead of formulating a constraint for each user to ensure that individual users are covered with a minimum probability β , we formulate a single constraint for the entire mmWave network that ensures that any arbitrarily selected user will be covered with this minimum probability β . Using various reformulation techniques, we equivalently reformulate our stochastic program as a binary linear program (BLP). Finally, we numerically analyze the performance of DBmWave under various system settings.

Note that in addition to user location, because of significant human-body shadowing in mmWave networks, user orientation is also a significant source of uncertainty. We have addressed this in some past work [64] and may integrate such considerations into this work in the future.

A. System Model

We consider a three-dimensional geographical area with a set $\mathcal{N} = \{1, 2, \dots, N\}$ of candidate locations for deploying mmWave APs on the ceiling to cover the floor, as depicted in Fig. 10. The floor is divided into $K = \frac{r_d}{2r_b} + \frac{1}{2}$ annuli, the i th annulus consists of M_i circles, where M_i is given by:

$$M_i = \left\lfloor \frac{2\pi}{2 \sin^{-1} \left(\frac{r_b}{r_d - 2r_b(K-i) - r_b} \right)} \right\rfloor = \left\lfloor \frac{\pi}{\sin^{-1} \left(\frac{1}{2(i-1)} \right)} \right\rfloor \quad (16)$$

r_d represents the radius of the geographical area and r_b is the radius of each circular area, as depicted in Fig. 10. We denote the set of circular areas by \mathcal{K} , where $|\mathcal{K}| = 1 + \sum_{i=2}^{\frac{r_d}{2r_b} + \frac{1}{2}} M_i$. The k th circular area in \mathcal{K} , denoted by A_k , is represented by a pair (i_k, j_k) , as illustrated in Fig. 10.

UEs are distributed in the geographical area according to the distribution $f_Z(z)$. The link between a mmWave AP placed at location $n \in \mathcal{N}$ and the k th circular area, $k \in \mathcal{K}$, if one of the AP beams is steered to cover A_k , is only available with probability p_{nk} . The maximum number of beams that a mmWave AP can have is denoted by B .

B. Problem Statement

Given \mathcal{N} , \mathcal{K} , B , β , $f_Z(z)$, and $p_{nk}, n \in \mathcal{N}, k \in \mathcal{K}$, we answer the following questions jointly while ensuring that an arbitrarily chosen user within the geographical area of interest will be covered with a probability $\geq \beta \in (0, 1)$.

- 1) What is the minimum number of required mmWave APs?
- 2) How can they be deployed optimally?

Fig. 10. Illustration of the system model considered in DBmWave.

3) *How can their beams be steered optimally?*

C. Problem Formulation

Let $y_{nk}, n \in \mathcal{N}, k \in \mathcal{K}$, be binary decision variables; y_{nk} equals one if a mmWave AP is placed at location n and one of its beams is steered to cover region k , and it equals zero otherwise. Let \mathbb{P}_{cov} be the network-wide coverage probability, i.e., the probability that an arbitrarily selected user in the network will be covered. Then, the joint AP deployment and beam steering problem can be formulated as:

Problem 1: Joint AP Deployment and Beam Steering

$$\min_{\{y_{nk}\}} \sum_{n \in \mathcal{N}} \left(\mathbb{1}_{\{\sum_{k \in \mathcal{K}} y_{nk} \geq 1\}} \right) \quad (17)$$

subject to:

$$\mathbb{P}_{\text{cov}} \geq \beta \quad (18)$$

$$\sum_{k \in \mathcal{K}} y_{nk} \leq B, \forall n \in \mathcal{N} \quad (19)$$

$$y_{nk} \in \{0, 1\}, \forall n \in \mathcal{N}, \forall k \in \mathcal{K} \quad (20)$$

where $\mathbb{1}_{\{\cdot\}}$ is an indicator function; $\mathbb{1}_{\{\cdot\}}$ equals one if $\{\cdot\}$ is satisfied and zero otherwise, and $\beta \in (0, 1)$.

1) *Coverage Probability Constraint:* As stated earlier, the coverage probability is defined as the probability that an arbitrarily selected user lies in a circular area that is covered by at least one active beam. Hence, the coverage probability when the arbitrarily selected user is located at z can be defined as:

$$\mathbb{P}_{\text{cov}}^{(z)} = \mathbb{E} \left[1 - \prod_{n \in \mathcal{N}} (1 - \delta_{nk(z)} y_{nk}) \right] \quad (21)$$

where $k^{(z)}$ is the index of the circular area that contains location z . $\delta_{nk(z)}$ equals one if there is no blockage between the AP candidate location n and the circular area $A_{k(z)}$, and it equals zero otherwise. The expectation in (21) is over blockages, which—similarly to Section III—are assumed to be independent across links. Therefore,

$$\mathbb{P}_{\text{cov}}^{(z)} = 1 - \prod_{n \in \mathcal{N}} (1 - p_{nk(z)} y_{nk}). \quad (22)$$

To compute the unconditioned coverage probability, we take the user distribution $f_Z(z)$ into consideration as follows:

$$\mathbb{P}_{\text{cov}} = 1 - \sum_{k \in \mathcal{K}} \left(\int_{A_k} f_Z(z) dz \prod_{n \in \mathcal{N}} (1 - p_{nk} y_{nk}) \right). \quad (23)$$

The integration $\int_{A_k} f_Z(z) dz$ over each circular area is upper-bounded by the integration over the sector enclosed in the i_k -th annulus between the two tangents of A_k , see (24). This upper

$$\begin{aligned}
\int_{A_k} f_Z(z) \, dz &\leq \left(a_{i_k} + 2 \sin^{-1} \left(\frac{1}{2(i_k - 1)} \right) \right) \int_{r_d - 2r_b(K - i_k)}^{r_d - 2r_b(K - i_k + 1)} \frac{f_{R_z}(r_z)}{2\pi} \, dr_z \\
&= \left(a_{i_k} + 2 \sin^{-1} \left(\frac{1}{2(i_k - 1)} \right) \right) \int_{2r_b(i_k - 1.5)}^{2r_b(i_k - 0.5)} \frac{f_{R_z}(r_z)}{2\pi} \, dr_z, \\
&\quad \forall 2 \leq i_k \leq K.
\end{aligned} \tag{24}$$

bound is used in our analysis to enhance tractability. This enables us to use the probability distribution $f_{R_z}(r_z)$, where $R_z = \|z\|$. The term $\left(2 \sin^{-1} \left(\frac{1}{2(i_k - 1)} \right) \right)$ in (24) represents the angle of the sector enclosed in the i_k -th annulus between the two tangents of A_k . The term a_{i_k} is added to ensure that $\sum_{k \in \mathcal{K}} \int_{A_k} f_Z(z) \, dz = 1$. In Section IV-D, the following two user distributions are investigated:

- *Truncated Gaussian distribution*, where $f_{R_z}^{\text{gaus}}(r_z) = \frac{r_z \exp\left(-\frac{r_z^2}{2\sigma^2}\right)}{\sigma^2 \left(1 - \exp\left(-\frac{r_d^2}{2\sigma^2}\right)\right)}$ and σ^2 represents the variance of the user distribution.
- *Uniform distribution*, where $f_{R_z}^{\text{unif}}(r_z) = \frac{2r_z}{r_d^2}$.

2) *Equivalent binary linear program*: First, note that the objective function of Problem 1 is non-linear. It can be represented in a linear form by introducing new binary decision variables, $x_n \triangleq \mathbb{1}_{\{\sum_{k \in \mathcal{K}} y_{nk} \geq 1\}}$, $\forall n \in \mathcal{N}$, and reformulating the indicator function as follows [69]:

- If $\sum_{k \in \mathcal{K}} y_{nk} \geq 1$ then $x_n = 1$ can be reformulated as:

$$\sum_{k \in \mathcal{K}} y_{nk} - (M + \epsilon) x_n \leq 1 - \epsilon \tag{25}$$

where M is an upper bound of $\sum_{k \in \mathcal{K}} y_{nk} - 1$ and $\epsilon > 0$ is a small tolerance beyond which we regard the constraint as having been broken. Selecting M and ϵ to be $B - 1$ and 1, respectively, (25) reduces to $\sum_{k \in \mathcal{K}} y_{nk} \leq B x_n$.

- If $x_n = 1$ then $\sum_{k \in \mathcal{K}} y_{nk} \geq 1$ can be reformulated as¹²:

$$\sum_{k \in \mathcal{K}} y_{nk} + m x_n \geq m + 1 \tag{26}$$

¹²Note that this condition is equivalent to $\sum_{k \in \mathcal{K}} y_{nk} = 0 \implies x_n = 0$, which is already enforced by the objective function, since it aims at minimizing the number of mmWave APs. Hence, (26) is redundant.

where m is a lower bound of $\sum_{k \in \mathcal{K}} y_{nk} - 1$. Selecting m to be -1 , (26) reduces to $\sum_{k \in \mathcal{K}} y_{nk} \geq x_n$. Therefore,

$$x_n = \mathbb{1}_{\{\sum_{k \in \mathcal{K}} y_{nk} \geq 1\}} \iff x_n \leq \sum_{k \in \mathcal{K}} y_{nk} \leq B x_n, \forall n \in \mathcal{N}.$$

Second, the coverage probability expression, \mathbb{P}_{cov} , has the term $\mathbb{P} \triangleq \prod_{n \in \mathcal{N}} (1 - p_{nk} y_{nk})$, which is nonlinear in the decision variables $y_{nk}, n \in \mathcal{N}, k \in \mathcal{K}$. Expanding \mathbb{P} , we can see that the nonlinear terms in \mathbb{P} are in the form of products of binary decision variables. For example, if $N = 3$, \mathbb{P} can be expressed as:

$$\mathbb{P} = 1 - \sum_{i=1}^3 p_{ik} y_{ik} + p_{1k} p_{2k} y_{1k} y_{2k} + p_{1k} p_{3k} y_{1k} y_{3k} + p_{2k} p_{3k} y_{2k} y_{3k} - \prod_{i=1}^3 p_{ik} y_{ik}. \quad (27)$$

To linearize a product of binary decision variables, say $\prod_{i=1}^N y_{ik}$, we introduce a new auxiliary non-negative decision variable, say y_k , replace $\prod_{i=1}^N y_{ik}$ by y_k , and add the following constraints:

$$\begin{aligned} y_k &\leq y_{ik}, \forall i \in \{1, 2, \dots, N\} \\ y_k &\geq \sum_{i=1}^N y_{ik} - (N - 1) \\ y_k &\geq 0. \end{aligned} \quad (28)$$

After reformulating the indicator function and \mathbb{P} , as explained above, Problem 1 becomes a BLP.

D. Numerical Analysis

1) *Setup:* Assuming an open indoor environment such as a cafeteria space, r_d and r_b were selected to be 5.5 and 0.5 meters, respectively. Based on these values, we calculated the number of circular areas, as explained in subsection IV-A, and found that $K = 92$. The maximum number of beams that a mmWave AP can have, B , is varied between 1 and 4. The APs are assumed to be mounted on the ceiling, which is $10 \times 10 \text{ m}^2$. The height of the ceiling is assumed to be 3 m, similarly to our measurement setup in Sections II and III. The APs are deployed in a grid-based manner, similarly to the indoor hotspot scenario presented in [17], that is, each candidate location is with equal distance to each other, as shown in Fig. 10. Two different user distributions were considered: (i) Gaussian distribution with mean $u = 0$ and variance $\sigma = 10$

and (ii) uniform distribution. The probabilities of link availabilities were calculated assuming three channel effects: pathloss, small-scale fading, and blockage (the event of a user having no LOS with a certain AP). We adopt the power-law pathloss model, as presented in (1). For LOS case, we set P_0 to 78.31 dB and n to 2.1. For NLOS case, we set P_0 to 95.39 dB and n to 3.5. We set d_0 to 1 m.

The small-scale fading is assumed to follow the $\kappa - \mu$ distribution given by (2). For LOS case, we set κ to 2.80, μ to 0.77, and Ω to 1.16. For NLOS case, we set κ to 0.92, μ to 0.96, and Ω to 1.23.

Similarly to Section III, blockages across the links between the mmWave APs and the coverage areas are modeled as independent and identically distributed (i.i.d.) Bernoulli random variables. p_{LOS} denotes the probability that there is no blockage on a certain link between an AP and a coverage area and $p_{NLOS} = 1 - p_{LOS}$ denotes the probability that there is a blockage on the link. In general, p_{LOS} varies from one link to another; for our numerical results, p_{LOS} is set to 0.5 for all the links. Moreover, frequency reuse factor is assumed to be $\ll 1$, i.e., interference is negligible. The Gaussian noise spectral density is set to -174 dBm/Hz.

While linearizing Problem 1 above, we assumed that, for each user, there are only three AP candidate locations that can cover it. These three AP locations form the best (most available) AP-user links (i.e., links with the highest $p_{n,k}$ values for a given k). We selected different values of N , the number of AP candidate locations, to better characterize the behavior of the system. We evaluated our stochastic optimization framework in terms of the required number of APs for different coverage probabilities β . The optimization problem was solved using CPLEX.

2) *Results:* Fig. 11(a) shows the number of required APs as a function of the minimum required coverage probability (β). In this figure, the number of AP candidate locations was chosen to be $N = 100$, the users were assumed to be distributed according to a Gaussian distribution. It can be seen that as β increases, more APs are needed to satisfy the coverage demand. Furthermore, increasing the number of beams at each AP reduces the required number of APs. This is expected, as having more beams at an AP allows it to cover more users.

Fig. 11(b) is similar to Fig. 11(a), but assuming the users to be uniformly distributed. Both figures show similar trends. However, the number of APs required to satisfy a certain coverage probability is higher when the users are uniformly distributed. In the case of Gaussian distribution, users are clustered in the geographical area (in contrast to the case of uniform distribution). This clustering results in reducing the number of required APs.

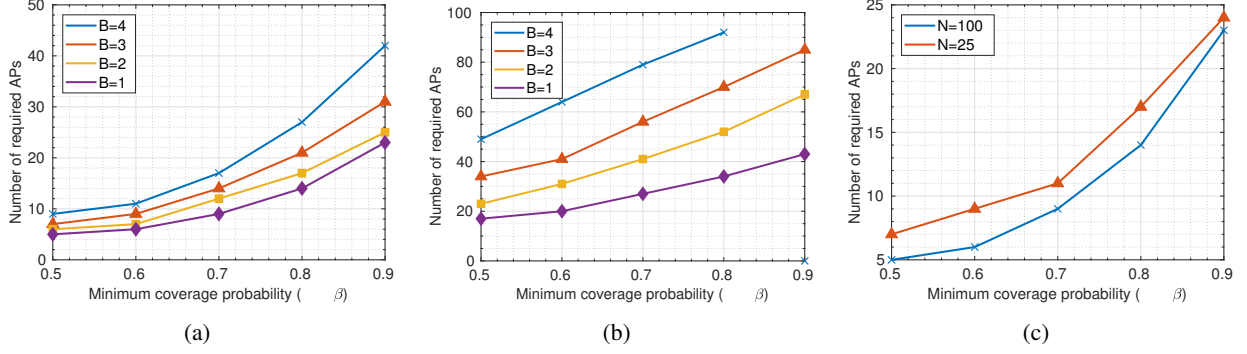

Fig. 11. Number of required APs vs. minimum coverage probability for: a) Gaussian distributed users, with $N = 100$ beams, b) uniformly distributed users, with $N = 100$ beams, and c) Gaussian distributed users and different values of N , with $B = 4$.

Finally, Fig. 11(c) illustrates the effect of the number of AP candidate locations on the number of required APs to meet a certain coverage probability. It can be seen that as N increases the number of required APs decreases. This is due to the fact that increasing N expands the feasibility region of the allocation problem, opening the room for better solutions (i.e., with lower objective function value).

V. DISCUSSION AND CONCLUDING REMARKS

In the preceding sections we described findings that pertain to various aspects of indoor mmWave network design. Crucially, we showed that indoor mmWaves deployments may achieve (or come close to achieving) performance targets of 1 Gbit/s EDR, and 15 Tbps/km² ATC [53]. Yet, this performance can be volatile to device usage scenarios. In this section, we bring together the results to discuss these trade-offs, and look more closely at any outstanding challenges.

A. Take Away Lessons

In the system-level analysis, e.g., in Fig. 6(c), we could see that sub-100% coverage for a probe user is easily achievable, even under the presence of body blockages Fig. 9(c). From the deployment analysis in Fig. 11(a) and Fig. 11(b), we see that this does not need to be the case if multiple users are considered. Covering each and every user above a certain reliability threshold may require deploying an excessively large number of access points, especially if we expect high reliability. Switching back to the system-level perspective, the increased number of transmitters will increase the network capacity, see Fig. 6(a), without deteriorating the rate for 5th percentile users, see Fig. 6(b). However, depending on the usage scenario the EDR may stay substantially

below the required performance. In Section IV we show that this can be avoided by coordinating deployment locations and beam steering according to the patterns of user locations (users that cluster in space) and user orientations (users that face single direction). This can be observed by comparing results in Fig. 11(a) and Fig. 11(b).

An alternative way to bring up the EDR for all usage cases is to increase the antenna gain by narrowing the transmission beamwidth. This, of course, will come at a cost of using more directional antennas or antenna arrays with larger number of components. In effect imposing even stricter requirements on beam alignment and tracking. As we observed, beam misalignments will render any indoor mmWave communication links effectively unusable. One simple solution to decrease the chances of beam misalignments is to use wider beams, which should improve the performance of beam tracking and association mechanisms (as reported in, e.g., [59]). Surprisingly this will not severely affect the coverage (with the exception of the Office hand scenario), but will, however, result in severe degradation of the network capacity and, as noted earlier, performance achievable by the worst-off users.

This scenario may be avoided by planning for lower coverage probability, which, as we could observe in Fig. 11(a), greatly reduces the number of necessary transmitters, leading to reduced interference and enabling us the usage of wider beams. We conclude that there is a trade-off between designing for beam alignment (or lack thereof) and capacity (and reliable coverage). While narrower beams compensate for smaller antenna apertures and extra absorption losses, wider beams help us to reach and maintain beam alignment and may produce an overall better link budget.

B. Future Challenges

1) *Correlation in Channels across Spectrum Bands:* One way to improve link availability and capacity of mmWave networks in the presence of body blockages is to utilize dual connectivity and carrier aggregation [70]. Modelling of the corresponding deployment scenarios will require new models of correlation in shadowing and fading across different spectrum bands. Presently we have a fairly good overall understanding of the quantitative differences in propagation between sub-6 GHz frequencies and mmWaves [71]. Yet, inter-frequency correlation in shadowing for different scenarios of human body blockage or fading statistics is still uncharted territory. This question could also be asked about correlation between channels from multiple non-co-located transmitters. Answers to these questions should be sought through extensive channel

measurement campaigns, involving multiple multi-band access points, as well as follow-up system-level analyses.

2) *Coexistence between 5G NR and WiFi*: One of the key issues to address when operating in mmWave unlicensed bands is coexistence with other wireless systems. For example, in the 60 GHz band where the 3GPP is planning to deploy NR-U (the unlicensed spectrum version of the 5G NR), mechanisms will have to be developed to enable coexistence with wireless local area networks like the IEEE Wireless Gigabit 802.11ad/ay [5], [6]. As a matter of fact, the European Telecommunications Standards Institute (ETSI) has already published a list of conformance requirements, which include limits on the maximum emitted power or channel sensing mechanisms, necessary to ensure fair coexistence between the systems operating in unlicensed mmWave bands [72]. Yet, more work is needed to understand the impact of these coexistence rules on the network performance and, ultimately, network design.

3) *Network Densification Limits*: Finally, in Fig. 6(a) we could see that the network capacity of our system increases with the number of transmitters. An interesting question is to ask about the asymptotic case, and the limits of network densification. In [73] it was observed that network densification is limited by the channel characteristics, and antenna heights. However, this result applies to networks operating over large areas and network settings that correspond to outdoor deployments, e.g., variable deployment heights of tens of meters above ground-level. One would expect that for ceiling-mounted mmWave networks, with highly directional beams, we can reach high deployment densities, without making the system interference-limited, and thus achieve high network capacities. Yet, this would make beam alignment and tracking more challenging, thus potentially limiting the achievable network capacity. Analysis of this network density asymptotic regime would likely require a new modelling framework.

APPENDIX A

PROOF OF LEMMA 1

The power received at the reference user (as provided in (6)), conditioned on the blockage state t and antenna gain g_i , is a product of the fading random variable and a constant. This allows us to express the PDF of $S_{i,t}$ using (5)

$$f_{S_{i,t}}(s) = \frac{\theta_1^{(\mu+1)/2}}{\vartheta_{i,t}^{(\mu+1)/2} \theta_2^{(\mu-1)/2}} s^{(\mu-1)/2} \exp\left(-\frac{\theta_1}{\vartheta_{i,t}} s - \theta_{2,t}\right) I_{\mu-1} \left(2\sqrt{\frac{\theta_{1,t}\theta_{2,t}s}{\vartheta_{i,t}}}\right), \quad (29)$$

where $\vartheta_{i,t} = g_i l_t(r_i)$, and I_{μ_t-1} is the modified Bessel function of the first kind and order $\mu_t - 1$.

Now, using the series representation of the modified Bessel function we get that

$$f_{S_{i,t}}(s) = \frac{\theta_{1,t}^{\mu_t} \exp(-\theta_{2,t})}{\vartheta_{i,t}^{\mu_t}} \sum_{l=0}^{\infty} \left(\frac{\theta_{1,t}^l \theta_{2,t}^l}{\vartheta_{i,t}^l \Gamma(\mu_t + l) l!} s^{\mu_t-1+l} \exp\left(-\frac{\theta_{1,t}}{\vartheta_{i,t}} s\right) \right) \quad (30)$$

Then the CDF of $S_{i,t}$ can be expressed as

$$\begin{aligned} \mathbb{P}(S_{i,t} > x) &= \int_x^{\infty} f_{S_{i,t}}(s) ds \\ &\stackrel{(a)}{=} \frac{\theta_{1,t}^{\mu_t} \exp(-\theta_{2,t})}{\vartheta_{i,t}^{\mu_t}} \sum_{l=0}^{\infty} \left(\frac{\theta_{1,t}^l \theta_{2,t}^l}{\vartheta_{i,t}^l \Gamma(\mu_t + l) l!} \int_x^{\infty} s^{\mu_t-1+l} \exp\left(-\frac{\theta_{1,t}}{\vartheta_{i,t}} s\right) ds \right) \\ &= \exp(-\theta_{2,t}) \sum_{l=0}^{\infty} \frac{\theta_{2,t}^l}{l!} \frac{\Gamma(l + \mu_t, \frac{\theta_{1,t}}{\vartheta_{i,t}} x)}{\Gamma(l + \mu_t)} \\ &\stackrel{(b)}{=} \exp(-\theta_{2,t}) \sum_{l=0}^{\infty} \frac{\theta_{2,t}^l}{l!} \sum_{n=0}^{l+\mu_t-1} \frac{1}{n!} \left(\frac{\theta_{1,t} x}{\vartheta_{i,t}} \right)^n \exp\left(-\left(\frac{\theta_{1,t}}{\vartheta_{i,t}}\right) x\right), \end{aligned} \quad (31)$$

where for (a) we use the expression in (30), and (b) holds only for the special case of μ_t being a positive integer.

APPENDIX B

PROOF OF LEMMA 2

In the following, given the distance to the serving transmitter r_0 , serving link gain g_0 , and the serving channel being in state t , and denoting the longer-term average power received from the serving transmitter as $\vartheta_{0,t} = g_0 l_t(r_0)$, we derive the conditional CCDF of the SINR as experienced by the reference user, i.e., $\mathbb{P}_{\text{cov}} = F_{\text{SINR}|R_0, G_0, T}^c(\zeta|r_0, g_0, t)$. For a given threshold ζ ,

this conditional CCDF can be defined as

$$\begin{aligned}
\mathbb{P}_{\text{cov}} &= \mathbb{P} \left(\zeta \cdot (I + \tau^{-1}) \right) \left(\sum_{l=0}^{\infty} \frac{\theta_{2,t}^l}{l!} \sum_{n=0}^{l+\mu_t-1} \frac{\mathbb{E} \left[\left(\frac{\zeta \theta_{1,t}}{\vartheta_{0,t}} (I + \tau^{-1}) \right)^n \exp \left(-\frac{\zeta \theta_{1,t}}{\vartheta_{0,t}} (I + \tau^{-1}) \right) \right]}{n!} \right) \\
&\stackrel{(a)}{=} \exp \left(-\theta_{2,t} - \frac{\zeta \theta_{1,t}}{\vartheta_{0,t} \tau} \right) \left(\sum_{l=0}^{\infty} \frac{\theta_{2,t}^l}{l!} \sum_{n=0}^{l+\mu_t-1} \frac{1}{n!} \left(\frac{\zeta \theta_{1,t}}{\vartheta_{0,t}} \right)^n \sum_{k=0}^n \binom{n}{k} \tau^{-n+k} \mathbb{E} [I^k \exp \left(-\frac{\zeta \theta_{1,t}}{\vartheta_{0,t}} I \right)] \right) \\
&= \exp \left(-\theta_{2,t} - \frac{\zeta \theta_{1,t}}{\vartheta_{0,t} \tau} \right) \left(\sum_{l=0}^{\infty} \frac{\theta_{2,t}^l}{l!} \sum_{n=0}^{l+\mu_t-1} \frac{1}{n!} \left(\frac{\zeta \theta_{1,t}}{\vartheta_{0,t} \tau} \right)^n \sum_{k=0}^n \binom{n}{k} \tau^k \right. \\
&\quad \left. \mathbb{E} \left[\sum_{i=1}^{n_{\text{TX}}} G_i H_{i,V} l_V(R_i) \right)^k \exp \left(-\frac{\zeta \theta_{1,t}}{\vartheta_{0,t}} \sum_{i=1}^{n_{\text{TX}}} G_i H_{i,V} l_V(R_i) \right) \right] \right) \\
&\stackrel{(b)}{=} \exp \left(-\theta_{2,t} - \frac{\zeta \theta_{1,t}}{\vartheta_{0,t} \tau} \right) \left(\sum_{l=0}^{\infty} \frac{\theta_{2,t}^l}{l!} \sum_{n=0}^{l+\mu_t-1} \frac{1}{n!} \left(\frac{\zeta \theta_{1,t}}{\vartheta_{0,t} \tau} \right)^n \sum_{k=0}^n \binom{n}{k} \tau^k \right. \\
&\quad \left. \sum_{k_1+k_2+\dots+k_{n_{\text{TX}}}=k} \binom{k}{k_1, k_2, \dots, k_{n_{\text{TX}}}} \prod_{1 \leq i \leq n_{\text{TX}}} \mathbb{E} \left[\left(G_i H_{i,V} l_V(R_i) \right)^{k_i} \exp \left(-\frac{\zeta \theta_{1,t}}{\vartheta_{0,t}} G_i H_{i,V} l_V(R_i) \right) \right] \right) \\
&\stackrel{(c)}{=} \exp \left(-\theta_{2,t} - \frac{\zeta \theta_{1,t}}{\vartheta_{0,t} \tau} \right) \left(\sum_{l=0}^{\infty} \frac{\theta_{2,t}^l}{l!} \sum_{n=0}^{l+\mu_t-1} \frac{1}{n!} \left(\frac{\zeta \theta_{1,t}}{\vartheta_{0,t} \tau} \right)^n \sum_{k=0}^n \binom{n}{k} \left(\sum_{k_1+k_2+\dots+k_{n_{\text{TX}}}=k} \binom{k}{k_1, k_2, \dots, k_{n_{\text{TX}}}} \right. \right. \\
&\quad \left. \left. \prod_{1 \leq i \leq n_{\text{TX}}} \left(\mathbb{E}_{V, G_i, R_i} \left[\frac{(\mu_V)_{k_i} \theta_{1,V}^{\mu_V} \exp(-\theta_{2,V}) (G_i l_V(R_i))^{k_i}}{\left(\frac{\zeta \theta_{1,t}}{\vartheta_{0,t}} G_i l_V(R_i) + \theta_{1,V} \right)^{k_i + \mu_V}} {}_1F_1 \left(k_i + \mu_V; \mu_V; \frac{\theta_{1,V} \theta_{2,V}}{\frac{\zeta \theta_{1,t}}{\vartheta_{0,t}} G_i l_V(R_i) + \theta_{1,V}} \right) \right] \right) \right) \right) \right)
\end{aligned} \tag{32}$$

where (a) comes from the binomial expansion, in (b) we apply the multinomial expansion and use the fact that antenna gains, channel fading, and distances are independent across all the interferers, (c) comes from taking the expectation with respect to the fading random variable (one can find it by either considering series representation of the PDF of fading or considering the integral in [74][Eq. 6.643.2]).

Now, the expectation in the final expression above is really the key component which captures three (at least potentially) random parameters of any interfering transmitter, which are the

blockage state, directionality and distance, i.e.:

$$\mathbb{I}_1 = \sum_{v \in \{\text{LOS}, \text{NLOS}\}} p_v \sum_{g \in \mathcal{G}} \left(p_g(\mu_v)_{k_i} \theta_{1,v}^{\mu_v} g^{k_i} \exp(-\theta_{2,v}) \times \right. \\ \left. \mathbb{E}_R \left[\left(\frac{l_v^k(R)}{\left(\frac{\zeta \theta_{1,t}}{\vartheta_{0,t}} g l_v(R) + \theta_{1,v} \right)^{k_i + \mu_v}} {}_1F_1 \left(k_i + \mu_v; \mu_v; \frac{\theta_{1,v} \theta_{2,v}}{\frac{\zeta \theta_{1,t}}{\vartheta_{0,t}} g l_v(R) + \theta_{1,v}} \right) \right] \right) \right) \quad (33)$$

where p_g corresponds to the directionality gain probability model, and p_v corresponds to the blockage probability model.

APPENDIX C

PROOF OF COROLLARY 1

We can find the expectation with respect to the distance of a user located in the center of a disk as follows:

$$\begin{aligned} \mathfrak{Z}_{k_i} &= \mathbb{E}_R \left[\left(\frac{(l_v(r))^{k_i}}{\left(\frac{\zeta \theta_{1,t}}{\vartheta_{0,t}} g l_v(r) + \theta_{1,v} \right)^{k_i + \mu_v}} {}_1F_1 \left(k_i + \mu_v; \mu_v; \frac{\theta_{1,v} \theta_{2,v}}{\frac{\zeta \theta_{1,t}}{\vartheta_{0,t}} g l_v(r) + \theta_{1,v}} \right) \right) \right] \\ &= \frac{2}{\rho^2} \int_0^\rho \left(\frac{(\gamma_v(r^2 + \eta)^{-\alpha_v/2})^{k_i}}{\left(\frac{\zeta \theta_{1,t}}{\vartheta_{0,t}} g \gamma_v(r^2 + \eta)^{-\alpha_v/2} + \theta_{1,v} \right)^{k_i + \mu_v}} {}_1F_1 \left(k_i + \mu_v; \mu_v; \frac{\theta_{1,v} \theta_{2,v}}{\frac{\zeta \theta_{1,t}}{\vartheta_{0,t}} g \gamma_v(r^2 + \eta)^{-\alpha_v/2} + \theta_{1,v}} \right) \right) \left(dr \right. \\ &\stackrel{(a)}{=} \frac{2\gamma_v^{k_i}}{\rho^2 \theta_{1,v}^{k_i + \mu_v}} \int_h^{\sqrt{\rho^2 + h^2}} \left(\frac{y^{-\alpha_v k_i + 1}}{\left(\frac{\zeta \theta_{1,t}}{\vartheta_{0,t} \theta_{1,v}} g \gamma_v y^{-\alpha_v} + 1 \right)^{k_i + \mu_v}} {}_1F_1 \left(k_i + \mu_v; \mu_v; \frac{\theta_{2,v}}{\frac{\zeta \theta_{1,t}}{\vartheta_{0,t} \theta_{1,v}} g \gamma_v y^{-\alpha_v} + 1} \right) \right) dy \\ &= \frac{2\gamma_v^{k_i}}{\rho^2 \theta_{1,v}^{k_i + \mu_v}} \sum_{j=0}^{\infty} \frac{(k_i + \mu_v)_j \theta_{2,v}^j}{(\mu_v)_j j!} \int_h^{\sqrt{\rho^2 + h^2}} \frac{y^{-\alpha_v k_i + 1}}{\left(\frac{\zeta \theta_{1,t}}{\vartheta_{0,t} \theta_{1,v}} g \gamma_v y^{-\alpha_v} + 1 \right)^{k_i + \mu_v + j}} dy \\ &\stackrel{(b)}{=} \frac{2\gamma_v^{k_i} y^{2 - k_i \alpha_v}}{\rho^2 \theta_{1,v}^{k_i + \mu_v} (2 - k_i \alpha_v)} \sum_{j=0}^{\infty} \frac{(k_i + \mu_v)_j \theta_{2,v}^j}{(\mu_v)_j j!} {}_2F_1(k_i + \mu_v + j, k_i - 2/\alpha_v; k_i - 2/\alpha_v + 1; -\frac{\zeta \theta_{1,t}}{\vartheta_{0,t} \theta_{1,v}} g \gamma_v y^{-\alpha_v}) \Big|_h^{\sqrt{\rho^2 + h^2}} \\ &\stackrel{(c)}{=} \frac{2\gamma_v^{k_i} y^{2 - k_i \alpha_v}}{\rho^2 \theta_{1,v}^{k_i + \mu_v} (2 - k_i \alpha_v)} \sum_{j=0}^{\infty} \sum_{l=0}^{\infty} \frac{(k_i + \mu_v)_j (k_i + \mu_v + j)_l (k_i - 2/\alpha_v)_l}{(\mu_v)_j (k_i - 2/\alpha_v + 1)_l j! l!} \theta_{2,v}^j \left(-\frac{\zeta \theta_{1,t}}{\vartheta_{0,t} \theta_{1,v}} g \gamma_v y^{-\alpha_v} \right)^l \Big|_h^{\sqrt{\rho^2 + h^2}} \\ &\stackrel{(d)}{=} \frac{2\gamma_v^{k_i} y^{2 - k_i \alpha_v}}{\rho^2 \theta_{1,v}^{k_i + \mu_v} (2 - k_i \alpha_v)} \Psi_1(k_i + \mu_v, k_i - 2/\alpha_v, \mu_v, k_i - 2/\alpha_v + 1; \theta_{2,v}, -\frac{\zeta \theta_{1,t}}{\vartheta_{0,t} \theta_{1,v}} g \gamma_v y^{-\alpha_v}) \Big|_h^{\sqrt{\rho^2 + h^2}}, \quad (34) \end{aligned}$$

where for (a) we use variable transformation $y = \sqrt{r^2 + \eta}$, (b) comes from [74, 3.194.1] and is valid for $k_i - 2/\alpha_v > 0$, (c) uses the series representation of the hypergeometric function, (d)

uses properties of the Humbert series Ψ_1 .

APPENDIX D

TABLE III: Notation Used

Symbol	Description
P	Pathloss (in dB)
P_0	Pathloss at the reference distance (in dB)
α	Pathloss exponent
d_0	Reference distance
d	Separation distance between the transmitter and receiver
κ	Ratio between the total power in the dominant signal components and the total power in the scattered signal components
μ	Number of multipath clusters
Ω	Mean signal power
n_{TX}	Number of APs
Φ	Set of APs (point process)
\mathcal{W}	Area considered
ρ_0	Distance between the reference user and the origin
ρ	Radius of the disk representing the considered area
r_i	Distance to the i -th AP
$h_{\text{TX(RX)}}$	Height of an AP (the reference user)
$\omega_{\text{TX(RX)}}$	Transmitter (receiver) beamwidth
$\mathbf{G}_{\text{TX(RX)}}$	Transmitter (receiver) mainlobe gain
$\mathbf{g}_{\text{TX(RX)}}$	Transmitter (receiver) sidelobe gain
G_i	Alignment gain with the i -th AP
p_{g_i}	PMF of the event $G_i = g_i$
p_{NLOS}	Blockage probability
$\gamma_{i,t}$	Pathloss at the reference distance given access point i and blockage state t
α_t	Pathloss exponent given blockage state t
$H_{i,t}$	Blockage-dependent power fading
$\{\kappa_t, \mu_t, \Omega_t\}$	Parameters of the fading model given blockage state t

$l_t(\cdot)$	Blockage-dependent pathloss
$S_{i,t}$	Received power from the i -th AP given blockage state t
SINR	SINR
I	Interference power
τ	Signal-to-Noise Ratio (SNR)
ζ	SINR threshold
$F_X^c(\cdot)$	CCDF of a r.v. X
C_{area}	ATC
$\lambda = \frac{n_{\text{TX}}}{ \mathcal{W} }$	AP density
bw	System bandwidth
SE	Spectral efficiency
$q_X(\beta)$	β -quantile of r.v. X
$f_X(\cdot)$	PDF of a r.v. X
\mathcal{N}	Set of candidate locations for deploying mmWave APs
K	Number of annuli constituting the floor of the considered area
M_i	Number of circles constituting the i -th annulus
r_d	Radius of the geographical area of interest
r_b	Radius of each circular area in the geographical area of interest
\mathcal{K}	Set of circular areas in the floor of the considered area
A_k	k -th circular area in \mathcal{K}
p_{nk}	Probability that the link between an AP at location n and A_k is available
B	Maximum number of beams that an AP can have
β	Requested coverage probability
\mathbb{P}_{cov}	Network-wide coverage probability

ACKNOWLEDGMENT

This material is based in part upon work supported by the National Science Foundation under grant CNS-1526844, the Science Foundation Ireland under grant 14/US/I3110 and the Department for the Economy Northern Ireland through grant USI080. The authors would also like to thank Shubhajeet Chatterjee and Fadhil Firyaguna, for their support at various stages of the manuscript preparation.

Jacek Kibilda is a Research Fellow with Trinity College Dublin and a 2017-18 Fulbright Scholar with the University of Texas at Austin. His research interests include applications of stochastic geometry and optimization to radio resource management and sharing for wireless and mobile networks. As a research lead on the NEMO project, he is applying his expertise to system-level analysis of mmWave networks.

Allen B. MacKenzie is a Professor in Electrical and Computer Engineering at Virginia Tech and the Associate Director of Wireless @ Virginia Tech. His research interests focus on wireless communications and networking and currently include the integration of mmWave technology into networks. He is the Principal Investigator of the NSF-funded NEMO project at Virginia Tech.

Mohammad J. Abdel-Rahman is an Associate Professor in the Electrical Engineering Department at Al Hussein Technical University (HTU), Amman, Jordan, an Associate Professor in the Computer Science Department at HTU, and an Adjunct Assistant Professor in the Electrical and Computer Engineering Department at Virginia Tech. His research interests focus on wireless communications and networking and currently include the integration of mmWave technology into networks.

Seong Ki Yoo is currently a Lecturer in the School of Computing, Electronics and Mathematics, Coventry University. His research interests include mmWave channel modelling and measurements, fading characterization for wearable and vehicular communications channels, future transport and cities, and performance analysis over fading channels.

Lorenzo Galati Giordano (M'15, SM'20) is currently Member of Technical Staff at Nokia Bell Labs Ireland since 2015. He received the M.Sc and the Ph.D degree in Communication Systems from Politecnico di Milano, Italy, respectively in 2005 and 2010. In 2008 he has been Marie-Curie short term fellow at Centre for Wireless Network Design, University of Bedfordshire (UK). Lorenzo has more than 10 years of academical and industrial experience in 4G and 5G system research, design and prototyping. His current research focus is on future indoor networks, next generation Wi-Fi and large antenna arrays solutions for the unlicensed spectrum.

Simon L. Cotton is a Reader in Wireless Communications with the Institute of Electronics, Communications, and Information Technology, Queen's University Belfast in the United Kingdom where he leads the Wireless Communications Laboratory. He is an expert in the area of channel characterization and modeling having authored and co-authored over 100 IEEE related publications on these topics. Dr Cotton currently holds two major grants funded in the area of mmWave communications with combined funding well in excess of £1 million. These projects are focused on understanding the role that mmWave technologies will play in future generations of cellular networks.

Nicola Marchetti is an Assistant Professor in Wireless Communications at Trinity College Dublin. He has authored in excess of 130 journals and conference papers, 2 books and 8 book chapters, holds 2 patents, and received 4 best paper awards. For the past few years, he has been performing research on system-level analysis and radio resource management of 4th Generation wireless (4G) and 5G indoor local area networks. In particular, he is a research lead in the NEMO project, coordinating the work on system-level modeling of mmWave indoor networks.

Walid Saad is an Associate Professor of ECE at VT. His research interests include wireless networks, network optimization, machine learning, and game theory. He has published over 250 conference and journal papers in these areas, including several best paper awards. He has substantial expertise on performance analysis and resource management for wireless networks, in general, and mmWave communications in particular.

William G. Scanlon (M'98SM'13) received the Ph.D. degree from Ulster University, UK in 1997. He was appointed as Lecturer at the University of Ulster in 1998, Senior Lecturer and Full Professor (Wireless Communications) at Queens University of Belfast (UK) in 2002 and 2008, respectively. He served as Research Director for Wireless Communication Systems, Director of the Centre for Wireless Innovation and Head of School of Electronics, Electrical Engineering and Computer Science while at Queens (2002-2018). He also held a part-time Chair in Short Range Radio at the University of Twente, The Netherlands from 2009 to 2014. He is currently Chief Executive Officer of Tyndall National Institute, Cork, Ireland. Professor Scanlon received a Young Scientist award from URSI in 1999, he was a recipient of the 2010 IEEE H. A. Wheeler Prize Paper Award for IEEE Trans. Antennas and Propagation and he delivered the 2012 NATO International Lecture Series on Next Generation Communications.

Adrian Garcia-Rodriguez is a Research Scientist in the Indoor Networks group of Nokia Bell Labs (Ireland), where he currently focuses on multi-antenna systems both at microwave and millimeter wave frequencies. He received the Ph.D. degree in Electrical and Electronic Engineering from University College London (UK) in 2016, with emphasis on massive MIMO. Adrian is a frequent tutorial speaker on unlicensed spectrum communications at IEEE conferences such as ICC, Globecom, and WCNC.

David López-Pérez (M'12, SM'17) is currently a member of Technical Staff at Nokia Bell Laboratories. Prior to this, David received the B.Sc. and M.Sc. degrees in telecommunication from Miguel Hernandez University, Spain, in 2003 and 2006, respectively, and the Ph.D. degree in wireless networking from the University of Bedfordshire, U.K., in 2011. David was also a RF Engineer with Vodafone, Spain, from 2005 to 2006, and a Research Associate with Kings College London, U.K., from 2010 to 2011. David has done extensive work on cellular small cell and ultra-dense network performance analysis.

Holger Claussen is leader of the Indoor Networks Research Department of Nokia Bell Labs located in Ireland and the US. He and his team are innovating in all areas related to future evolution, deployment, and operation of wireless networks to enable exponential growth in data traffic. Holger received his Ph.D. degree in digital communications from the University of Edinburgh, United Kingdom in 2004. He is author of 1 book, more than 110 publications and 120 filed patent families.

Luiz A. DaSilva holds the chair of Telecommunications at Trinity College Dublin, where he is the Director of CONNECT, a telecommunications centre funded by the Science Foundation Ireland. His area of expertise is distributed and adaptive resource management in wireless networks, and in particular radio resource sharing and the application of game theory to wireless networks. Prof. DaSilva is a Fellow of Trinity College Dublin, an IEEE Communications Society Distinguished Lecturer and a Fellow of the IEEE, for contributions to cognitive networks and to resource management in wireless networks. He has previously published three papers in the Proceedings of the IEEE (among more than 200 peer-reviewed papers) and is the Principal Investigator, at Trinity College, of the Science Foundation Ireland-funded NEMO project, which investigates the integration of mmWave networks with other wireless technologies operating below 6 GHz.
